

Account Class

Part I: Create a class to model an Account.

It should have the following private instance fields:

balance (double) , accountNumber (int)

It should have one default constructor.

It should have one constructor which sets the balance via parameter.

It should have the following methods:

getBalance – returns balance

deposit – takes a double parameter and uses it to change the balance

withdraw – takes a double parameter and uses it to change the balance

transfer – which takes an account object parameter and a double parameter and transfers out of “this” account and into the account referenced by the parameter

printSlip – prints all fields in an appropriate way

Part II:

Create a test class for the Account class. In this test class do the following.

Create an Account object with a balance of \$100 and reference it as ac1.

Print the account information.

Deposit \$300 into the account and then print its slip again.

Withdraw \$23.45 and then print its slip again.

Create another Account object using your default constructor, reference it as ac2.

Transfer \$25 in funds from ac1 to ac2 using your transfer method.

Once all of that is complete, investigate withdrawing another \$1000 and look at the result. What might need to be done to prevent this?
